Target Population:
These recommendations apply to patients, with a history of primary cancer of the breast, who are suspected of having metastatic/recurrent breast cancer.

Recommendations:

- Where feasible, all patients with a history of breast cancer, suspected of having recurrent/metastatic disease should undergo a biopsy and retesting for the presence of ER, PR, and HER2 receptors;
- For patients who have an apparent gain of a receptor following testing, a physician-patient discussion should occur regarding the implications for management strategies;
- Despite the lack of evidence to suggest an improvement in progression-free survival (PFS) or OS with the addition of anti-hormonal and/or anti-HER2 therapy for those with receptor gain, the poorer expected prognosis for these patients suggests that doing so would be a reasonable approach.

Note: At present, there is not enough evidence to support the discontinuation of endocrine therapy or HER2-directed therapy in patients with an apparent loss of a receptor.

Supporting Evidence:
Knowing that discordance may exist between primary and metastatic cancers of the breast is important, but more so if this knowledge can be used to alter the clinical management of the patient. Recent studies indicated that 12% to 20% of those patients with pathologically confirmed discordance had a change in their treatment plan, such as endocrine therapy, trastuzumab, and/or chemotherapy, based on the results of the biopsy (2-6). A large pooled analysis of two recent prospective studies, reporting on the ER/PR/HER2 receptors in matched primary and recurrent breast cancer, included the United Kingdom’s Breast Recurrence In
Tissues Study (BRITS) and the Canadian DESTINY study (2,3,7). The authors reported that the usual reasons for a treatment plan alteration was a change in HER2 status, gain of hormone receptor, the identification of a benign lesion or a second malignancy. One prospective study found that 10% of patients suspected of having metastatic breast cancer, were subsequently found to have either benign disease or another malignant process (2). Therapy was most often changed when there was an apparent gain of a receptor, allowing for the introduction of other treatment options such as endocrine therapy or trastuzumab. The recent GEICAM 2009-03 ConvertHER study, the largest prospective trial of its kind, which evaluated conversion rates of ER/PR/HER2 receptors was the only study that compared the expression results of 31 local laboratories to those obtained at a single central laboratory (8). Though the conversion rates were lower at the central lab when compared with local labs, the discrepancies in receptor results (ER 13% vs 21%, PR 28% vs 35%, HER2 3% vs 16% respectively) were similar to those found in the pooled analysis of the BRITS and DESTINY studies described above. This trial found 4% of patients also had a clinical misdiagnosis of recurrent breast cancer. Though lower than the 10% reported above, it still highlights the importance of biopsy for differential diagnosis.

One of the DESTINY study’s investigational endpoints was to assess the impact of discordance on patient management and survival (3). It found that if treatment were altered according to discordant results between primary and metastatic disease, there were no apparent differences in TTF (time to treatment failure) or OS (overall survival) between patients with concordant and discordant disease. The authors did admit that the power of their study to detect such differences were low. Retrospective studies, however, have shown with consistency that poorer survival has been found to be associated with positive to negative ER switches and a lower likelihood of responding to anti-hormonal therapy (5,9-12). Data from retrospective studies found a similar trend of shorter overall survival for patients whose HER2 status switched from positive to negative compared to patients that switched from negative to positive or were concordant (13-15).

Bone-only metastatic disease from a breast primary may be problematic in terms of obtaining accurate ER, PR and HER2 results from a CNB. The tissue obtained from the biopsy requires decalcification and the acid-based solution used to do this, also reduces the immunoreactivity of most antigens which limits an accurate assessment of the receptors (16).

**Qualifying Statements:**

The potential benefits of having patients with a history of breast cancer, undergo a biopsy of suspected recurrent or metastatic disease include:

- Identification of benign lesions that may have been assumed to be metastatic;
- Identification of a second malignancy unrelated to original breast cancer requiring a different plan of care;
- Provision of more accurate treatment regimens if discordant results are found;
- Allows clinicians to more accurately discuss prognosis with the patient allowing more informed treatment decisions in conjunction with maintaining quality of life.

**Disclaimer:**

These guidelines are a statement of consensus of the Breast Disease Site Group regarding their views of currently accepted approaches to diagnosis and treatment. Any clinician seeking
to apply or consult the guidelines is expected to use independent medical judgment in the context of individual clinical circumstances to determine any patient’s care or treatment.
